

# Machine Learning for Graphs and Sequential Data

## *Graphs - Ranking*

Lecturer: Prof. Dr. Stephan Günnemann

[cs.cit.tum.de/daml](https://cs.cit.tum.de/daml)

---

Summer Term 2023

# Roadmap

---

- **Chapter: Graphs**

1. Graphs & Networks
2. Generative Models
- 3. Ranking**
4. Clustering
5. Classification (Semi-Supervised Learning)
6. Node/Graph Embeddings
7. Graph Neural Networks (GNNs)

# Motivation: Ranking of Nodes

- How to organize the Web?
- First try: Human curated Web directories
  - Yahoo, DMOZ, LookSmart
- Second try: Web Search
  - Information Retrieval investigates: Find relevant docs in a small and trusted set
    - Newspaper articles, Patents, etc.
  - But: **Web is huge**, full of untrusted documents, randomness, web spam, etc.
- Web pages are not equally “important”
  - `www.some-personal-website.com` vs. `www.tum.de`
- There is large diversity in the web-graph node connectivity.  
Let's rank the pages by the link structure!

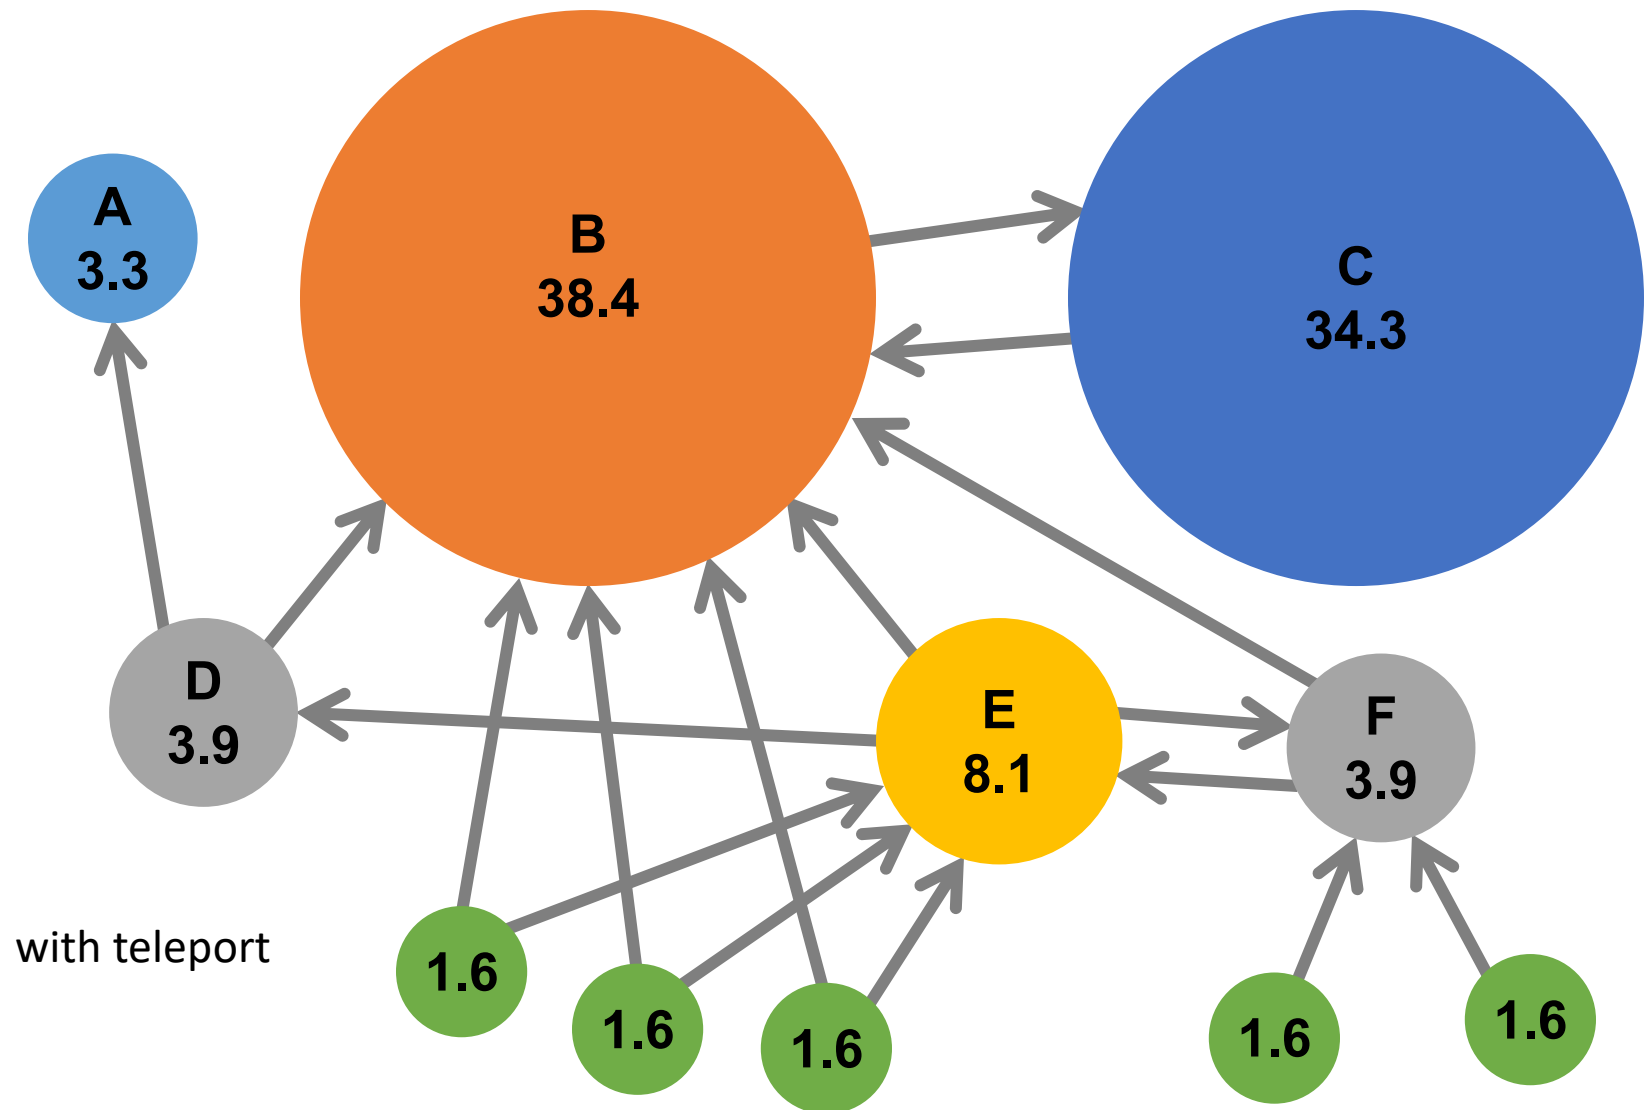

# PageRank

- Core idea: **A page is important if many important pages point to it**
  - recursive formulation
  
- "Voting" principle
  - each page votes for the importance of the pages it points to
  - a link's vote is proportional to the importance of its source page
  - If page  $j$  with importance  $r_j$  has  $n$  out-links, each link gets  $\frac{r_j}{n}$  votes
  - Page  $j$ 's own importance is the sum of the votes on its in-links
  
- Rank of page  $j$ :  $r_j = \sum_{i \rightarrow j} \frac{r_i}{d_i}$ 
  - $d_i$  ... out-degree of node  $i$

$$r_j = r_i/3 + r_k/4$$

## Example: PageRank Scores

# Computation via Solving Equations

- Rank of page  $j$ :  $r_j = \sum_{i \rightarrow j} \frac{r_i}{d_i}$ 
  - $d_i$  ... out-degree of node  $i$
  
- Example:
  - 3 equations, 3 unknowns, no constants
    - No unique solution
    - All solutions equivalent modulo a scale factor
  - Additional constraint forces uniqueness:  $\sum_i r_i = 1$
  - Solution:  $r_y = \frac{2}{5}$ ,  $r_a = \frac{2}{5}$ ,  $r_m = \frac{1}{5}$
  
- Gaussian elimination method works for small examples but we need a better method for large web-size graphs

## Equations:

$$r_y = r_y/2 + r_a/2$$

$$r_a = r_y/2 + r_m$$

$$r_m = r_a/2$$

# PageRank: Matrix Formulation

- Stochastic adjacency matrix  $M$ 
  - If  $i \rightarrow j$ , then  $M_{ji} = \frac{1}{d_i}$  else  $M_{ji} = 0$
  - $M$  is a column stochastic matrix
    - Columns sum to 1
- Rank vector  $r$ 
  - $r_i$  is the importance score of page  $i$
  - $\sum_i r_i = 1$
- Equations  $r_j = \sum_{i \rightarrow j} \frac{r_i}{d_i}$  can be written as:
 
$$r = M \cdot r$$

$$M = \begin{matrix} & \begin{matrix} y & a & m \end{matrix} \\ \begin{matrix} y \\ a \\ m \end{matrix} & \begin{bmatrix} 1/2 & 1/2 & 0 \\ 1/2 & 0 & 1 \\ 0 & 1/2 & 0 \end{bmatrix} \end{matrix}$$

$$r = M \cdot r \quad \begin{bmatrix} r_y \\ r_a \\ r_m \end{bmatrix} = \begin{bmatrix} 1/2 & 1/2 & 0 \\ 1/2 & 0 & 1 \\ 0 & 1/2 & 0 \end{bmatrix} \begin{bmatrix} r_y \\ r_a \\ r_m \end{bmatrix}$$

# Computation via Eigenvector

- Equations can be written as:  $\mathbf{r} = \mathbf{M} \cdot \mathbf{r}$
  
- The rank vector  $\mathbf{r}$  is an eigenvector of the stochastic matrix  $\mathbf{M}$ 
  - eigenvector with corresponding eigenvalue 1
  - Math background: largest eigenvalue of  $\mathbf{M}$  is 1 since  $\mathbf{M}$  is column stochastic (with non-negative entries)
    - We know  $\mathbf{r}$  is unit length and each column of  $\mathbf{M}$  sums to one, so  $\mathbf{M}\mathbf{r} \leq \mathbf{1}$
  
- Finding  $\mathbf{r}$  = finding eigenvector of  $\mathbf{M}$  corresponding to the largest eigenvalue
  - you know how to do this efficiently (power iteration; see ML slides)

# Notes on Computation

- Power iteration: iteratively compute  $\mathbf{r} \leftarrow \frac{\mathbf{M} \cdot \mathbf{r}}{\|\mathbf{M} \cdot \mathbf{r}\|}$  until convergence
  - required for PageRank:  $\sum_i r_i = 1$
- Let  $\mathbf{y} = \mathbf{M} \cdot \mathbf{x}$  with  $\sum_i x_i = 1$ .  
 Since  $\mathbf{M}$  is column stochastic, it holds  $\sum_i y_i = 1$
- No need for normalization!
- Start with random (normalized) vector  $\mathbf{r}$ , and iterate  $\mathbf{r} \leftarrow \mathbf{M} \cdot \mathbf{r}$
- Important: Matrix  $\mathbf{M}$  is sparse!
  - we only need to consider the (ingoing) neighbors of each node
- Iteratively compute  $r_j \leftarrow \sum_{i \rightarrow j} \frac{r_i}{d_i}$  until convergence
  - first compute the updated value for each  $r_j$ , then assign them at once

$$\mathbf{r} = \mathbf{M} \cdot \mathbf{r}$$

$$\begin{bmatrix} r_y \\ r_a \\ r_m \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & 0 & 1 \\ 0 & \frac{1}{2} & 0 \end{bmatrix} \begin{bmatrix} r_y \\ r_a \\ r_m \end{bmatrix}$$

# Random Walk Interpretation

- Consider a random web surfer that moves between the web pages
  - At time  $t$ , the web surfer is in a random webpage  $i$
  - At time  $t + 1$ , the surfer follows an out-link from  $i$  uniformly at random
  
- The surfer's path (denoted by  $X_1, X_2, X_3, \dots$ ) forms a Markov chain
  - Web pages are the states of the Markov chain
  - The surfer starts from a random webpage:  $\Pr(X_1 = i) = \pi_i$
  - Transition probabilities:  $\Pr(X_{t+1} = j | X_t = i) = M_{ji}$
  - Note: the transition probability matrix of the Markov chain is  $\mathbf{B} = \mathbf{M}^T$

# Random Walk Interpretation

- Stationary distribution: the vector  $\pi^\infty$  is called stationary distribution if the following equality holds

$$\pi^\infty = \pi^\infty B$$

- By definition,  $\pi^\infty$  (if exists) is equal to (transpose of) the rank vector  $\mathbf{r}$ .
- $\pi^\infty$  can be computed by
  - getting the eigenvector of  $\mathbf{M}$  associated with the unit eigenvalue
  - normalizing it to one.

# Random Walk Interpretation

- Consider a random web surfer that moves between the web pages
    - The surfer's path (denoted by  $X_1, X_2, X_3, \dots$ ) forms a Markov chain
  
  - Remember:  $\Pr(X_t = i) \stackrel{\text{def}}{=} \pi_i(t)$ 
    - probability of reaching state  $i$  (here: page  $i$ ) in step  $t$
- recap:  
 $\boldsymbol{\pi}(t) = \boldsymbol{\pi} \mathbf{B}^{(t-1)}$
- What happens if the surfer is doing infinitely many steps?
    - $\lim_{t \rightarrow \infty} \boldsymbol{\pi}(t)$  is called the limiting distribution (if it exists)
  
  - Under some “technical conditions”, a Markov chain has a limiting distribution which is equal to its unique stationary distribution
    - we have  $\mathbf{r} = \lim_{t \rightarrow \infty} \boldsymbol{\pi}(t)$  // rank score of page  $i = r_i = \lim_{t \rightarrow \infty} \Pr(X_t = i)$
    - limit of the sequence  $\boldsymbol{\pi} \mathbf{B}, (\boldsymbol{\pi} \mathbf{B}) \mathbf{B}, ((\boldsymbol{\pi} \mathbf{B}) \mathbf{B}) \mathbf{B}, \dots$  equals to  $\mathbf{r}$

# Random Walk Interpretation

- Given the “technical conditions” we have  $\mathbf{r} = \lim_{t \rightarrow \infty} \boldsymbol{\pi}(t)$ 
  - limit of the sequence  $\boldsymbol{\pi}\mathbf{B}$ ,  $(\boldsymbol{\pi}\mathbf{B})\mathbf{B}$ ,  $((\boldsymbol{\pi}\mathbf{B})\mathbf{B})\mathbf{B}$ , ... equals to  $\mathbf{r}$
- Probability of reaching a node does not depend on start point of surfer
  
- Intuition: Assume that when  $t \rightarrow \infty$ ,  $\mathbf{B}^t$  converges to a matrix whose rows are the same. In this case: one row of  $\lim_{t \rightarrow \infty} \mathbf{B}^t$  specifies the limiting distribution.

$$\lim_{t \rightarrow \infty} \mathbf{B}^{(t-1)} = \begin{bmatrix} a & b & c \\ a & b & c \\ a & b & c \end{bmatrix} \Rightarrow \lim_{t \rightarrow \infty} \boldsymbol{\pi}(t) = \lim_{t \rightarrow \infty} \boldsymbol{\pi} \mathbf{B}^{(t-1)} = \left( \begin{bmatrix} \pi_1 & \pi_2 & \pi_3 \end{bmatrix} \begin{bmatrix} a & b & c \\ a & b & c \\ a & b & c \end{bmatrix} \right) = \begin{bmatrix} a & b & c \end{bmatrix}$$

# Existence and Uniqueness

- What are the “technical conditions”?
  - Being **Irreducible** and **Aperiodic**
- **Irreducible**: it is possible to get to any state from any state
- **Aperiodic**: a state  $i$  is aperiodic if there exists  $n$  such that for all  $n' \geq n$ :  
 $\Pr(X_{n'} = i | X_1 = i) > 0$ 
  - A Markov chain is aperiodic if every state is aperiodic
  - An irreducible Markov chain only needs one aperiodic state to imply all states are aperiodic

# PageRank: Problems

- Some pages are dead ends (have no out-links)
  - Random walk has “nowhere” to go to
  - Such pages cause importance to “leak out”
  
- Spider traps: (all out-links are within the group)
  - Random walk gets “stuck” in a trap
  - And eventually spider traps absorb all importance
  
- Periodic states:
  - If we start at the state, we will return to the state in fixed periods.

# Solution: Random Teleports

- At each step, random surfer has **two options**:
  - With probability  $\beta$ , follow a link at random
  - With probability  $1 - \beta$ , jump to some random page

- PageRank equation [Brin-Page, 98]

$$r_j = \sum_{i \rightarrow j} \beta \frac{r_i}{d_i} + (1 - \beta) \frac{1}{N}$$

$$// = \sum_{i \rightarrow j} \beta \frac{r_i}{d_i} + \sum_i (1 - \beta) \frac{r_i}{N}$$

- In matrix notation:  $A = \beta M + (1 - \beta) \begin{bmatrix} 1/N \\ \vdots \\ 1/N \end{bmatrix}_{N \times N}$

$[1/N]_{N \times N}$  is a  
N by N matrix  
where all entries  
are  $1/N$

- final solution:  $\mathbf{r} = \mathbf{A} \cdot \mathbf{r}$

*This formulation assumes that  $\mathbf{M}$  has no dead ends. We can either preprocess matrix  $\mathbf{M}$  to remove all dead ends or explicitly follow random teleport links with probability 1.0 from dead-ends.*

# Illustration: Random Teleports ( $\beta = 0.8$ )

# Notes on Computation

- Attention: **The matrix  $\mathbf{A}$  is dense!**
  - $N^2$  non-zero entries
  - you should never compute  $\mathbf{r}$  in such a way
  
- Consider the teleport by adding constant penalty to each term
  - iterate  $r_j \leftarrow \sum_{i \rightarrow j} \beta \frac{r_i}{d_i} + (1 - \beta) \frac{1}{N}$  until convergence
  - only neighbors need to be considered
  
- To maintain sparsity in matrix form multiply by  $\beta \mathbf{M}$  then add a vector
  - $\mathbf{r} = \beta \mathbf{M} \mathbf{r} + (1 - \beta) \left[ \frac{1}{N} \right]_N$
  
- **Vertex-oriented computation**
  - each vertex performs local computations

# Systems/Frameworks for Graph Processing

- Specialized systems for such kind of graph processing
  - *GraphLab* (Dato, Turi)
  - *Giraph* (open source counterpart to Google's Pregel)
  - *GraphX*: Library for graph processing on top of Spark
- **Crucial aspect: vertex-oriented programming**
  - each vertex performs local computations
  - GAS principle — **gather, apply, scatter**: each vertex (a) gathers information from adjacent vertices/edges (b) applies transformation, (c) scatters information to adjacent vertices
  - for PageRank only steps a + b required
- Similar concepts become also more frequent in Deep Learning Frameworks due to popularity of Graph Neural Networks

# Some Problems with Page Rank

---

- Measures generic popularity of a page
  - Biased against topic-specific authorities
  - Solution: Topic-Sensitive PageRank
- Susceptible to Link spam
  - Artificial link topographies created in order to boost PageRank
  - Solution: TrustRank
- Uses a single measure of importance
  - Other models of importance
  - Solution: Hubs-and-Authorities (HITS, Hyperlink-Induced Topic Search)

# Topic-Sensitive PageRank

- Instead of **generic popularity**, can we measure popularity **within a topic**?
  - Goal: Evaluate Web pages not just according to their popularity, but by how close they are to a particular topic, e.g. “sports” or “history”
  - Allows search queries to be answered based on **interests of the user**
- Core idea: **Bias the random walk**
  - When walker teleports, pick a page from a set  $S$
  - **Standard PageRank**:  $S$  = all pages
    - any page with equal probability
  - **Topic-Sensitive PageRank**:  $S$  = set of “relevant” pages
    - E.g., Open Directory (DMOZ) pages for a given topic/query
  - For each teleport set  $S$ , we get a different vector  $\mathbf{r}_S$

# Generalizing Topic-Sensitive PageRank

- As a matrix equation topic-sensitive PageRank takes the following form

$$r = \beta M r + (1 - \beta) \pi \quad \text{where } \pi_i = \begin{cases} \frac{1}{|S|} & \text{if } i \in S \\ 0 & \text{otherwise} \end{cases}$$

- We can generalize this further to arbitrary teleport vectors  $\pi$

$$r = \beta M r + (1 - \beta) \pi \quad \text{where } \sum_i \pi_i = 1$$

- The exact solution is  $r = (1 - \beta)(I - \beta M)^{-1} \pi$ 
  - Runtime scales worse than  $O(N^2)$
  - Use the iterative approximate algorithm in practice
    - Multiply by  $\beta \cdot M$ , then add restart vector  $(1 - \beta)\pi$ , repeat, ...
    - Maintains sparsity

# Example: Topic-Sensitive PageRank

Suppose  $S = \{1\}$ ,  $\beta = 0.8$

Node	Iteration				
	0	1	2	...	stable
1	0.25	0.4	0.28		0.294
2	0.25	0.1	0.16		0.118
3	0.25	0.3	0.32		0.327
4	0.25	0.2	0.24		0.261

$S = \{1\}$ ,  $\beta = 0.90$ :  
 $r = [0.17, 0.07, 0.40, 0.36]$   
 $S = \{1\}$ ,  $\beta = 0.8$ :  
 $r = [0.29, 0.11, 0.32, 0.26]$   
 $S = \{1\}$ ,  $\beta = 0.70$ :  
 $r = [0.39, 0.14, 0.27, 0.19]$

$S = \{1,2,3,4\}$ ,  $\beta = 0.8$ :  
 $r = [0.13, 0.10, 0.39, 0.36]$   
 $S = \{1,2,3\}$ ,  $\beta = 0.8$ :  
 $r = [0.17, 0.13, 0.38, 0.30]$   
 $S = \{1,2\}$ ,  $\beta = 0.8$ :  
 $r = [0.26, 0.20, 0.29, 0.23]$   
 $S = \{1\}$ ,  $\beta = 0.8$ :  
 $r = [0.29, 0.11, 0.32, 0.26]$

# Discovering the Topic Set S

---

- **Create different PageRanks for different topics**
  - The 16 DMOZ top-level categories:
    - arts, business, sports,...
  
- **Which topic ranking to use?**
  - User can pick from a menu
  - Classify query into a topic
  - Can use the **context** of the query
    - E.g., query is launched from a web page talking about a known topic
    - History of queries e.g., “basketball” followed by “Jordan”
  - User context, e.g., user’s bookmarks, ...

# PageRank: Variants (I)

- **“Normal” PageRank:**

- Teleports uniformly at random to any node
- All nodes have the same teleport probability of surfer landing there:

$$\pi = (0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1 \quad 0.1)^T$$

- **Topic-Sensitive PageRank:**

- Teleports to a topic specific set of pages
- Nodes can have different probabilities of surfer landing there:

$$\pi = (0.1 \quad 0 \quad 0 \quad 0.2 \quad 0 \quad 0.5 \quad 0 \quad 0 \quad 0 \quad 0.2)^T$$

- **Personalized PageRank (Random Walk with Restarts):**

- Teleport is always to the same node:

$$\pi = (0 \quad 0 \quad 0 \quad 1 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0)^T$$

# PageRank: Variants

---

- Spam is common in the web
  - Spammer's goal: Maximize the PageRank of target page  $t$
  - Technique:
    - Get as many links from accessible pages as possible to target page  $t$
    - Construct “link farm” to get PageRank multiplier effect
  
- Combating link spam via TrustRank
  - **Topic-sensitive PageRank with a teleport set of trusted pages**
  - Example: .edu domains, similar domains for non-US schools

# Summary

---

- Core idea: Ranking of the nodes based on the link structure
- PageRank scores nodes depending on their incoming links
- With a teleport set we can rank nodes based on arbitrary factors, for example
  - Topic
  - Trust
  - Node identity
- Computing PageRank requires sparse matrix products for even moderately sized graphs

# Questions

---

- Consider a directed cycle of length 3 as a Markov chain disregarding edge weights

- Is it irreducible? Is it aperiodic?
- How does the introduction of random teleports change the above 3-cycle?
- How can you make it aperiodic by inserting just a single edge?
